A Survey on Security and Privacy Issues of Bitcoin

Mauro Conti, Senior Member, IEEE, Sandeep Kumar E, Member, IEEE, Chhagan Lal, Member, IEEE, Sushmita Ruj, Senior-Member, IEEE

Abstract—Bitcoin is a popular “cryptocurrency” that records all transactions in an distributed append-only public ledger called “blockchain”. The security of Bitcoin heavily relies on the incentive-compatible distributed consensus protocol which is run by participants called “miners”. In exchange of the incentive, the miners are expected to honestly maintain the blockchain. Since its launch in 2009, Bitcoin economy has grown at an enormous rate is now worth about 40 billions of dollars. This exponential growth in the market value of Bitcoin motivates adversaries to exploit weaknesses for profit, and researchers to identify vulnerabilities in the system, propose countermeasures, and predict upcoming trends.

In this paper, we present a systematic survey on security and privacy aspects of Bitcoin. We start by presenting an overview of the Bitcoin protocol and discuss its major components with their functionality and interactions. We review the existing vulnerabilities in Bitcoin which leads to the execution of various security threats in Bitcoin system. We discuss the feasibility and robustness of the state-of-the-art security solutions. We present privacy and anonymity considerations, and discuss the threats to enabling user privacy along with the analysis of existing privacy preserving solutions. Finally, we summarize the critical open challenges, and suggest directions for future research towards provisioning stringent security and privacy techniques for Bitcoin.

Keywords—Bitcoins, cryptocurrency, security threats, user privacy

I. INTRODUCTION

DIGITAL transactions and online trading are gaining a lot of interest in e-commerce society. In such electronic payment systems, a third party authenticator governs online trading. This trusted interference of an authenticator increases the cost of trading because a nominal fee is deducted as a payment or commission by these third parties. In 2008, a new concept called “Bitcoins” was introduced [1] that avoids this excessive cost caused by transaction fee. Bitcoin is a cryptographically secure decentralized peer-to-peer (P2P) electronic payment system, and it enables transactions involving virtual currency in the form of digital tokens. Such digital tokens, also called Bitcoin Coins (BTCs) are cryptocurrencies whose implementation relies on cryptography techniques. The cryptography is used in order to control the generation of new coins and to securely validate the transactions without involving any central authorities. In Bitcoin, the trust in a third-party such as a bank is replaced by a cryptographic proof-of-work (PoW) scheme that uses a public digital append-only ledger called blockchain. This ledger keep records for all coin balances and transactions in the whole Bitcoin system that are announced, agreed upon, and that are completed in the past. The blockchain is accessible to all the network nodes (or participants) in order to enforce transparency in the system.

In [2], authors claim that “Bitcoin works in practice and not in theory” due to lack of security research to find out theoretical foundation for Bitcoin protocols. Until today, due to incomplete existence of robust theoretical base, security research community were dismissing the use of Bitcoin. However, online communities have started adapting Bitcoin because it will soon take over the online trading business. For instance, “Wiki leaks” request its users to donate using the coins. The request quote is “Bitcoin is a secure and anonymous digital currency. Bitcoins cannot be easily tracked back to you, and are safer, and are faster alternative to other donation methods”. Wiki leaks also support the use of Litecoin, another cryptocurrency, for the same reason [3].

The Bitcoin technology is grabbing the attention of government bodies as they are being used to undermine legal controls. In [4], authors call Bitcoins “Enigmatic and Controversial Digital Cryptocurrency” due to mysterious concepts underneath the Bitcoin system and severe opposition from government. According to [5], the Bitcoin exchange trading reached to 23 billion from 15 billion in 2014, but at the end of fourth quarter of 2015, there was a drop in the trade. However, it is estimated that in 2017, Bitcoin technology will gain large number of users because of the techniques that it is going to adapt will be promising and novel [6]. For instance, the real-world deployment of a Bitcoin Point of Sale (PoS) terminal to buy coffee is successfully working since 2014 [7]. Additionally, recent research indicates that the Bitcoin techniques such as blockchain and consensus protocols will be envisioned in various existing applications which includes smart trading in smart grids [8], Internet of Things (IoT) [9] [10], vehicular networks [11], healthcare data management and smart cities [12] [13], to name a few.

Bitcoin payment system is a decentralized architecture without a trusted third party. Hence, it is favorite to hackers or
advertisers. The Bitcoin protocols are threatened by attacks of various forms at different stages of its operations. As length of popularity largely depends on the amount of security built on the system which surpasses all the other benefits of Bitcoin, therefore the main aim of this paper is to understand, the associated security and privacy issues that are linked with Bitcoin along with its required supportive background concepts. In this paper, we present a comprehensive survey specifically targeting the security and privacy aspects in Bitcoin. We discuss the state-of-the-art attack vector which includes various user security and transaction anonymity threats that limits (or threatens) the applicability (or continuity) of Bitcoins in real-world applications and services. We also discuss the efficiency of various security solutions that are proposed over the years to address the security and privacy challenges in Bitcoin system. In particular, we mainly focus on the security challenges and their countermeasures with respect to major components of Bitcoin system that includes transaction, Blockchain, mining pools, and Bitcoin’s networking protocols. In addition, we discuss the issues of user privacy and transaction anonymity along with a large array of research that has been done recently for enabling privacy and improving anonymity in Bitcoins. In [14], for the first time authors present a comprehensive technical survey on decentralized digital currencies with mainly emphasizing on Bitcoins. Authors explore the technical background of Bitcoin system and discuss the implications of the central design decisions for Bitcoin protocols. In [2], authors discuss the cryptocurrencies and Bitcoin in detail, and also provides a preliminary overview of the Bitcoin’s payment systems pros and cons. However, the paper lacks a detailed survey about security and privacy attacks and their associated solutions. In particular, the main contributions that this survey provides are as follow.

- We present the required background knowledge for Bitcoin, its functionalities and related concepts,
- We cover all the existing security and privacy related threats that are associated with different components of Bitcoin system at various levels of its overall operation, and
- We discuss the efficiency and limitations of the state-of-the-art solutions that addresses the security threats and enables strong privacy in Bitcoin systems, thus providing a holistic technical perspective on these issues in Bitcoin.

By doing so, we aim to assist interested readers in understanding existing security and privacy related challenges, estimate the possible damage caused by these, and to improve the techniques for detection and containment of identified existing and future attacks in Bitcoins.

The rest of the paper is organized as follow. In Section II, we present a brief overview of Bitcoin which includes the description of its major components along with their functionalities and interactions. In Section III, we discuss a number of security threats associated with the development, implementation and use of Bitcoin systems. In Section IV, we discuss the state-of-the-art proposals that either countermeasure a security threat or enhances the existing security in Bitcoins. In Section V, we discuss the anonymity and privacy threats in Bitcoins along with their existing solutions. We point out the potential lessons learned from our survey, and the future research directions towards enhancement of security and privacy in today’s Bitcoin system in Section VI. Finally, we conclude the paper in Section VII.

II. OVERVIEW OF BITCOIN

Bitcoin is a decentralized electronic payment system introduced by Nakamoto [1], it is based on peer-to-peer network and a probabilistic distributed consensus protocol. In Bitcoin, electronic payments are done by generating transactions that transfer coins among Bitcoin users. The source and destination addresses are represented by a cryptographic hash of a public key of the respective user. A user can have multiple addresses by generating multiple public keys and these addresses are associated be one or more of her wallets [15], but the private key of the user is required to spend coins in form of the digitally signed transactions. Using the hash of the public key as a receiving or sending address provides Bitcoin users a certain degree of anonymity, and it is recommended practice to use different public keys for each transaction. In a Bitcoin system, there are three major components namely, users (or customers), miners, management staff, Bitcoin exchanges and wallets. Figure 1 shows the main functions and means to achieve those functions for all these components.

A transaction to transfer the coins consist of a set of inputs and outputs, and it has a unique identifier. Each output depicts the amount sent and the script program\(^1\), whereas each input specifies a pointer to a previous transaction’s outputs and a corresponding signature (e.g., the redeem script) that satisfies all the required spending requirements i.e., one cannot spend more Bitcoins than specified in the inputs. Transactions are processed to verify their integrity, authenticity and correctness by a group of resourceful Bitcoin network nodes called “Miners”. In particular, instead of mining a single transaction, the miners bundle a number of transactions that are waiting in the network to get processed in a single unit called “block”. The miner advertises a block to the rest of the Bitcoin network as soon as it completes its processing (or validation) in order to claim the mining rewards. This block is then verified by the majority of miners in the network before it is successfully added in the globally-readable distributed Bitcoin public ledger called “blockchain”. The miner who mines a block receives a reward or incentive when the mined block is successfully added in the blockchain. We now present an overview of the major technical components and operational features that are essential for the practical realization of the Bitcoin systems.

A. Transaction and Proof-of-Work

Bitcoin uses transactions to move coins from one user wallet to another. In particular, the coins are represented in the form of transactions, more specifically, a chain of transactions. The

\(^1\) The script programs used in Bitcoin are (i) the “Pay-to-PubKeyHash” that requires a signature corresponding to an address, and (ii) the “Pay-to-script hash” that also enables multi-signature addresses by requiring a threshold of \(m\) signatures from \(n\) public keys.
key values in a transaction are one or more inputs, one or more outputs, and a unique transaction identifier ($T_x_id$) as depicted in Figure 2. Briefly, each input belongs to a particular user, and it specifies the unspent coins, the hash of its previous transaction, and an index to one of its output. To authorise a transaction input, the corresponding user of the input provides the public key and the signature which is generated using her private key. As an input specifies the total number of unspent coins of a user, therefore in each transaction, the user has to operate on all of its remaining coins. For instance, if Bob has 50 coins, and he wants to transfer 5 coins to Alice. For this transaction, Bob has to make two different inputs, one showing a transaction in which 5 coins are transfered to Alice and other showing a transfer of 45 coins in one (or more) wallet(s) owned by Bob. With this approach, the Bitcoin achieves two goals: (i) it implements the idea of change, and (ii) one can easily identify the unspent coins or balance of a user by only looking the outputs of its previous transaction. An output in a transaction specifies the number of coins being transfered along with the Bitcoin address of the new owner. These inputs and outputs are managed using a Forth-like scripting language which dictates the essential conditions to claim the coins. The dominant script in today’s market is the “Pay-to-PubKeyHash” (P2PKH) which requires only one signature from the owner to authorise a payment, while other script such as the “Pay-to-ScriptHash” (P2SH) [16] enables a variety of transaction types and it supports future developments.

Unlike central bank in which all the transactions are verified, processed, and recorded in a centralized private ledger, in Bitcoin every user acts as a bank and keep a copy of this ledger. In Bitcoin, the role of the distributed ledger is played by the so-called blockchain. However, storing multiple copies of the blockchain in the Bitcoin network adds new vulnerabilities in the system such as keeping the global view of the blockchain consistent. For instance, a user (say Alice) could generate two different transactions simultaneously using the same set of coins (called double spending) to two different receivers (say, Bob and Carol). If both the receiver processes the transaction independently based on their local view of the blockchain, and the transaction verification is successful, this leaves the blockchain into an inconsistent state. The main requirement to avoid the above problem is two-folded: (i) distribute the transaction verification process to ensure the correctness of the transaction, and (ii) everyone in the network should know quickly about a successfully processed transaction to ensure the consistent state of the blockchain. To fulfill the aforementioned requirements, Bitcoin uses the concept of Proof-of-Work (PoW) and a probabilistic distributed consensus protocol.

The distributed transaction verification process ensures that a majority of miners will verify the legitimacy of a transaction before it is added in the blockchain. In this way, whenever the blockchain goes into inconsistent state, all the nodes update their local copy of blockchain with the state on which a majority of miners agree, thus the correct state of the blockchain is obtained by election. However, this scheme is vulnerable to the sybil attacks [17]. With sybil attack, a miner creates multiple virtual nodes in the Bitcoin network and these nodes could disrupt the election process by injecting false information in the network such as voting positive for a faulty transaction. Bitcoin counts the sybil attacks by making use of PoW in which to verify a transaction, the miners has to perform some sort of computational task to prove that they are not virtual entities. The PoW consists of a complex cryptographic math puzzle [18], and it imposes a high level of computational cost on the transaction verification process, thus the verification will be dependent on the computing power of a miner, instead on the number of (possibly virtual) identities. The main idea is that it is much harder to fake the computing resources in the Bitcoin network than it is to perform a sybil attack.
Fig. 3. Bitcoin transaction execution process: A high-level view

In practical, the miners do not verify individual transactions, instead they collect pending transactions to form a block. The miners validate a block by calculating the hash of that block and vary a nonce value until the hash value becomes lower or equal to the given target value. Calculating the desired hash value is computationally difficult. Bitcoin uses the SHA-256 hash function [19]. Unless the cryptographic hash function finds the required hash value, the only option is to try different nonces until a solution (hash value lower than target value) is discovered. Consequently, the difficulty of the puzzle depends on the target value, i.e., lower the target, the less solutions exist, the more difficult the hash calculation becomes. Once a miner calculate such a hash value for a block, it immediately broadcast the block in the network along with the calculated hash value, and it also append the block in the public ledger (i.e., blockchain). The rest of the miners when receive a mined block can quickly verify its correctness by comparing the hash value given in the received block with the target value. The miners will also update their local blockchain by adding the newly mined block. Once a block is successfully added in the blockchain (i.e., a majority of miners consider the block valid), the miner who first solved the PoW will be rewarded with a set of newly generated coins and a small transaction fee [20].

All the miners race to calculate the hash value for a block by performing the PoW, so that they can collect the corresponding reward. The chance of being the first to solve the puzzle is higher for the miners who posses more number of computing resources. By this rule, a miner with higher computing resources can always increase her chances to win the reward. To enforce stability, fairness, and reasonable waiting times for block validation, the target value is adjusted after every 2,016 blocks. This adjustment of target also helps to keep per block verification time to approximately 10 minutes. It further effects the new coins generation rate in the Bitcoin network because keeping the block verification time near to 10 minutes implies that only 12.5 new coins can be added in the network per 10 minutes. In [21], authors propose an equation to calculate the new target value for the Bitcoin system. The new target is given by the following Equation.

$$T = T_{prev} \cdot \frac{T_{actual}}{2016 \cdot 10 min}$$

Here, $T_{prev}$ is the old target value, and $T_{actual}$ is the time period that the Bitcoin network took to generate the last 2,016 blocks.

B. Blockchain and Mining

The blockchain is a public append-only link-list based data structure which stores the entire network’s transaction history in terms of blocks that combines the transactions in a Merkle Tree [22]. Along with each block a relatively secure timestamp and the hash of the previous block is also stored. Figure 4 shows the working methodology that has been used for creating and maintaining the blockchain in Bitcoin. To successfully add a new block in the blockchain, the miners need to verify (or mine) a block by solving a computationally difficult PoW puzzle. One can traverse the blockchain in order to determine the ownership of each coin because the blocks are stored in an ordered form. Also, tempering within a block is not possible as it would change the hash of the block. In particular, if a transaction in a block is tampered with, the hash value of that block changes, this in turn changes the subsequent blocks. The blockchain constantly grows in length due to the continuous mining process in the network. The process of adding a new block is as follows: (i) once a miner determines a valid hash value (i.e., a hash equal or lower than target) for a block, it adds the block in her local blockchain and broadcast the solution, and (ii) upon receiving a solution for a valid block, the miners will quickly check for its validity, if the solution is correct the miners update their local copy of blockchain else discard the block.

Due to the distributed nature of the block validation process, it is possible that two valid solutions are found approximately at the same time or distribution of a verified block is delayed due to network latency, hence it creates valid blockchain forks of equal lengths. The forks are undesirable as the miners need to keep a global state of the blockchain that is consisting of the totally ordered set of transactions. However, when multiple forks exist, the miners are free to choose a fork and continue to mine on top of it. Now that the network is having multiple forks and miners are extending different but valid versions of the blockchain based on their local view, a time will come due to the random nature of PoW where miners of operating (or extending) one fork will broadcast a valid block before the others. Thus, a longer version of the blockchain is now existed in the network, and due to the blockchain’s consensus protocol all the miners will start adding their next blocks on top of it. The aforementioned blockchain forking nature of Bitcoin could be exploited by a malicious miner to gain profits or to disturb normal functioning of the Bitcoin systems. In particular, a resourceful miner (or mining pool) could force a blockchain fork in the Bitcoin network by privately mining
on it to increase its length. Once the malicious miner sees that the length of the public blockchain is catching up fast with her private chain, the miner broadcasts her chain into the Bitcoin network, and due to its longer length all the other miners have to mine on top of it. In this process, all the mined (i.e., valid) blocks on the other parallel blockchain gets discarded which makes the efforts of the genuine miners useless. In Section III, we will discuss an array of attacks on Bitcoin systems that are launched using the blockchain’s forking feature. In general, the security in Bitcoin systems is on the assumption that the honest players control majority of the computing resources.

The main driving factor for miners to honestly verify a block is the reward (i.e., 12.5 BTCs) that they receive upon their every successful addition of a block in the global blockchain. As mentioned before that to verify a block, the miners need to solve the associated hard crypto-puzzle. The probability to solving the crypto-puzzle is proportional to the amount of computing resources used. As per [23], a single home miner which uses a dedicated ASIC for mining will unlikely verify a single block in years. For this reason, miners mine in the form of the so-called mining pools. All miners that are associated with a pool works collectively to mine a particular block under the control of a pool manager. Upon a successful mining, the manager will distribute the reward between all the associated miners proportional to the resources expended by each miner. A detailed discussion of different pooled mining approaches and their reward systems is given in [24] [25].

Finally, for better understanding the overall methodology of Bitcoin payment system please refer to Figure 5. Let’s assume that Bob wants to send 50 coins to Alice. In order to pay to Alice, Bob needs a device such as a smartphone, tablet, or laptop that runs the Bitcoin’s client-side software, and two pieces of information which includes Bob’s private key and Alice’s public key (also called as a Bitcoin address). Any user in the Bitcoin network can send money to a Bitcoin address, but only a unique signature generated using her own private key can release coins from her account. When Bob create and broadcast a transaction in the Bitcoin network, an alert is sent to all the miners in the network, informing them about this new transaction. The miners verify that Bob has sufficient funds in order to complete the transaction by traversing into the blockchain (i.e., by checking its previous transaction outputs). Miners race to bundle all the pending transactions (including Bob’s) in the Bitcoin network and begin the block verification process by varying the nonce. The required hash value must have a certain but arbitrary number of zeros at the beginning. It’s unpredictable which nonce has correct number of zeros, so the miners has to keep trying by using different nonces to find the right value. When the miner finds a hash value with the correct number of zeros (i.e., the discovered value is lower than target value), the discovery is announced in the network, and both the Bob and the Alice will also receive a confirmation about the successful transaction^3. Other miners

\footnote{Such a successful transaction could be discarded or deemed invalid at latter period of time if it is unable to stay in the blockchain due to reasons such as, existence of multiple forks, majority of miners does not agree to consider the block containing this transaction a valid block, a double spending attack is detected, to name a few.}
communicate their acceptance, and they turn their attention to finding the next hash value for the next block of non-verified transactions. The Bitcoin protocol rewards the winning miner with the set of newly created coins as incentive, and the hashed block is published in the public ledger. Within 10 minutes\(^4\) of Bob initiating the transaction, he and Alice each receives the first confirmation that the Bitcoin was signed over to her. In terms of transaction time, the worst case is where the users have to wait for 10 minutes for the first confirmation as the mining process might involve the first time miners, else the time would be less. However, receiving the first confirmation does not mean that the transaction is processed successfully, and it cannot be invalidated at latter point of time. In particular, it has been recommended by the Bitcoin community that after a block is mined, it should receive enough consecutive block confirmations (currently 6 confirmations) before the transactions in it are treated as a valid transactions. This means on average it takes around one hour to safely assume that a transaction is validated successfully.

C. Advantages and Disadvantages

Like any other emerging technology, use of Bitcoin comes with certain pros and cons, and various types of risks are associated with its use. It is believed\(^5\) that Bitcoin has the following pros and cons.

**Pros:**
- no intermediate organization can manipulate the currency or can have a hold on the transactions since every currency transfer happens peer-to-peer just like hard cash,
- anonymity and privacy are the major strengths of these kinds of virtual currencies. Transacting peers are pseudonymous since the transaction is via digitally signed coins which looks like a sequence of characters to an outsider, and
- promotes a global economy that works everywhere, anytime, and with minimal processing fees.

**Cons:**
- the Bitcoin’s mining process is governed by a crypto-puzzle, it is a strength; however, it consumes computing resources and require time (atleast 10 mins) before confirming a transaction,
- since there is no trusted third party like a bank, if password of crucial credentials are lost the user completely loses access to his account. Additionally, any crime and illegal transactions will possibly go unnoticed,
- Bitcoin transactions are irreversible i.e., no refunds unless the receiver starts a new transaction to send the coins back to the sender, and
- use of Bitcoin encourages illicit activity such as money laundering, tax evasion, and illicit trade.

According to [26], the risk is the exposure to the level of danger associated with Bitcoin technology; in fact the same can be applied to any such digital cryptocurrency. The major risks that threatens the wide usability of the Bitcoin payment systems are as follow.

**Social risks:** it includes bubble formation (i.e., risk of socio-economic relationship such as what people talk and gossip), cool factor (i.e., entering the networking without knowing the ill effects), construction of chain

---

\(^4\)https://data.bitcoinity.org/bitcoin/block_time/5y?f=m10&t=l

\(^5\)As some of these pros and cons are not entirely true at all the times, for instance Bitcoin transactions are not fully anonymous and the privacy of Bitcoin users could be threatened.
(i.e., risk related with the blockchain formation like hashing and mining rewards), and new coins release (i.e., on what basis the new coins to be generated, is there a need etc.),

- **Legal risks:** Bitcoin technology opposes rules and regulations, and hence it finds opposition from the government. This risk also includes law enforcement towards handling financial, operational, customer protection and security breaches that arises due to Bitcoin system,

- **Economic risks:** deflation, volatility and timing issues in finding a block which might lead the users migrate towards other currencies that offer faster services.

- **Technological risks:** this includes the following, network equipments and its loss, network with which the peers are connected and its associated parameters, threat vulnerabilities on the system, hash functions with its associated robustness factor, and software associated risks that Bitcoin system demands,

- **Security risks:** security is a major issue in Bitcoin system, we will discuss risks associated due to various security threats in detail in Section III,

In [27], authors perform a survey on the people’s opinion about Bitcoin usage. Participants argue that the greatest barrier for the usage of Bitcoin is the lack of support by higher authorities (i.e., government). Participants felt that Bitcoin must be accepted as legitimate and reputable currency. Additionally, the participants expressed that the system must provide support towards transacting fearlessly without criminal exploitation. Participants further state that the Bitcoin is mainly dependent on the socio-technical actors, and the impact of their opinion on the public. Few among participants have suggested that the blockchain construction is the major cause of disruption due to its tendency to get manipulated by adversaries.

In [28], it was stated that many Bitcoin users already lost their money due to poor usability of key management and security breaches, such as malicious exchanges and wallets. Around 22.5% of the participants reported to have lost their coins due to security breaches. Also, many participants stated that for a fast flow of Bitcoins in the user community, simple and impressive user interface are even more important than security. In addition, participants highlighted that the poor usability and lack of knowledge regarding the Bitcoin usage are the major contributors for the security failures.

### III. Security: Attacks on Bitcoin Systems

Bitcoin is the most popular cryptocurrency and has stood first in the market capital investment from day one. Since, it is a decentralized model with an uncontrollable environment, hackers and thieves find cryptocurrency system an easy way to fraud the transactions. In this section, we discuss existing security threats and their countermeasures for Bitcoin system. We will provide a detailed discussion on potential vulnerabilities that can be found in the Bitcoin protocols as well as in the Bitcoin network, this will be done by taking a close look at the broad attack vector, and their impact on the particular components of the Bitcoin system. Apart from double spending, which is and will always be possible in Bitcoin, the attack space includes a range of wallet attacks (i.e., client-side security), network attacks (such as DDoS sybil and eclipse) and mining attacks (such as 50%, block withholding and bribery). Table I provides a comprehensive overview of the potential security threats along with their impacts on various entities involved in the Bitcoin system and their possible solutions that exists in the literature so far.

#### A. Double Spending

A client in the Bitcoin network achieves a double spend (i.e., send two conflicting transactions in rapid succession), if she is able to simultaneously spend the same set of coins in two different transactions [29]. For instance, a dishonest client \((C_d)\) creates a transaction \(T^C_{V,d}\) at time \(t\) using a set of coins \((B_c)\) with a recipient address of a vendor \((V)\) to purchase some product from \(V\). \(C_d\) broadcast \(T^C_{V,d}\) in the Bitcoin network. At time \(t'\) where \(t' \approx t\), \(C_d\) create and broadcast another transaction \(T^C_{d,J}\) using the same coins (i.e., \(B_c\)) with the recipient address of \(C_d\) or a wallet which is under the control of \(C_d\). In the above scenario, the double spending attack performed by \(C_d\) is successful, if \(C_d\) tricks the \(V\) to accept \(T^C_{V,d}\) (i.e., \(V\) deliver the purchased products to \(C_d\)) but \(V\) will not be able to redeem subsequently. In Bitcoin, the network of miners verify and process all the transactions, and they ensure that only the unspent coins that are specified in previous transaction outputs can be used as input for a follow-up transaction. This rule is enforced dynamically at run-time to protect against the possible double spending in Bitcoin networks. The distributed time-stamping and consensus protocol is used for orderly storage of the transactions in the blockchain. For example, when a miner receives \(T^C_{V,d}\) and \(T^C_{d,J}\) transactions, it will be able to identify that both the transactions are trying to use the same inputs during the transaction propagation and mining, thus it only process one of the transaction and reject the other. Figure 6 shows the working methodology of a double spending attack depicting the above explanation.

![Fig. 6. Double Spending Attack](image)

Despite the use of strict ordering of transactions in blockchain, proof-of-work scheme, distributed time-

stamping [72], and consensus protocol [73] [74], double spending is still possible in Bitcoin network. To perform a successful double spending attack, following requirements need to be fulfilled: (i) part of the Bitcoin miners network accepts the transaction \( T_{v}^{C_d} \) and the vendor (\( V \)) receives the confirmation from the miners, thus releases the product to dishonest client (\( C_d \)), (ii) at the same time, part of the Bitcoin miners network accepts the transaction \( T_{v}^{C_d} \), thus create blockchain forks in the network, (iii) the vendor receives the confirmation of transaction \( T_{v}^{C_d} \) after accepting the transaction \( T_{v}^{C_d} \), thus losses the product, and (iv) a majority of miners mine on top of the blockchain which contains \( T_{v}^{C_d} \) as a valid transaction. If the aforementioned steps took place in the given order then the dishonest client is able to perform a successful double spend in the Bitcoin network. In the rest of this section, we will discuss the variants of double spending attack that are used in order to realize the aforementioned double spend requirements with varying difficulties and complexities.

A form of double spending called Finney attack [33], here a dishonest client (\( C_d \)) pre-mines (i.e., privately) a block which contains the transaction \( T_{v}^{C_d} \), and then it creates a transaction \( T_{v}^{C_d} \) using the same coins for a vendor (\( V \)). The mined block is not informed to the network, and the \( C_d \) waits until the transaction \( T_{v}^{C_d} \) is accepted by the \( V \). On the other hand, \( V \) only accepts \( T_{v}^{C_d} \) when it receives a confirmation from miners indicating that \( T_{v}^{C_d} \) is valid and included in the existing blockchain. Once \( C_d \) receives the product from \( V \), the attacker releases the pre-mined block into the network, thus creates a blockchain fork (say \( B_{fork}^{C_d} \)) of equal length to the existing fork (say \( B_{fork} \)). Now, if the next mined block in the network extends \( B_{fork}^{C_d} \) blockchain instead of \( B_{fork} \), than as per the Bitcoin protocol rules all the miners in the network will build on top of \( B_{fork}^{C_d} \). As the blockchain \( B_{fork}^{C_d} \) becomes the longest chain in the network, all the miners ignore \( B_{fork}^{C_d} \), thus the top block on \( B_{fork}^{C_d} \) which contains the transaction \( T_{v}^{C_d} \) becomes invalid. This makes the transaction \( T_{v}^{C_d} \) invalid, the client will get back her coins through transaction \( T_{v}^{C_d} \), but resulting the \( V \) losing the product. With Finney attack an adversary can only perform double spending in the presence of one-confirmation vendors.

To avoid the Finney attack, the vendor should wait for multiple confirmations before releasing the product to the client. The waiting for multiple confirmations will only make the double spend for the attacker more harder, but the possibility of the double spend remains. An advancement of the Finney attack is called Brute-force attack [34] in which a resourceful attacker has control over \( n \) nodes in the network, and these nodes collectively works on a private mining scheme with the motive of double spend. An attacker introduces a double spend transaction in a block as in the previous case, while continuously works on the extension of a private blockchain (i.e., \( B_{fork}^{C_d} \)). Suppose a vendor waits for \( x \) confirmations before accepting a transaction, and it sends the product to the client once it receives the \( x \) confirmations. Later, if the attacker is able to mine \( x \) number of blocks ahead (i.e., privately) then she can release these blocks in the network, and due to its higher length than \( B_{fork} \), blockchain \( B_{fork}^{C_d} \) will be extended by all the miners in the network. This causes the same after effects as Finney attack, thus causing a successful double spending attack.

Another attack that uses privately mined block to perform a new form of double spending attack on Bitcoin exchange networks is popularly known as Vector 76 attack [35]. In this attack, a dishonest client (\( C_d \)) withholds a pre-mined block which consists of a transaction that implements a specific deposit (i.e., deposit coins in a Bitcoin exchange). The attacker (i.e., \( C_d \)) waits for the next block announcement and quickly sends the pre-mined block along with the recently mined block directly to the Bitcoin exchange or towards its nearby peers with hope that the exchange and probably some of the nearby miners will consider the blockchain containing the pre-mined block (i.e., \( B_{fork}^{C_d} \)) as the main chain. The attacker quickly sends another transaction that requests a withdrawal from the exchange for the same coins that was deposited by the attacker in its previous transaction. At this point of time, if the other fork (i.e., \( B_{fork}^{C_d} \)) does not contains the transaction that is used by the attacker to deposit the coins survives, the deposit will become invalidated but the attacker has already performed a withdrawal by now, thus the exchanges loses the coins. Recently, authors in [75] proposes a new attack against the PoW mechanism in blockchain systems called the Balance attack. The attack consists of delaying network communications between multiple subgroups of miners with balanced hash power. The theoretical analysis provides the precise trade-off between the Bitcoin network communication delay and the mining power of the attacker(s) needed to double spend in Ethereum [76] with high probability.

Based on the above discussion on double spending attack and its variants, one main point that emerges is that if, a miner (or mining pool) is able to mine blocks with a faster rate than the rest of the Bitcoin network, the possibility of a successful double spending attack is high. The rate of mining a block depends upon solving the associated proof-of-work, this again depends on the computing power of a Bitcoin node. Apart from the computing resources, the success of double spending attack depends on other factors as well which includes network propagation delay, vendor, client and Bitcoin exchange services connectivity or positioning in the Bitcoin network, and the number of honest miners. Clearly, as the number of confirmations for a transaction increases, the possibility that it will become invalid at a later stage decreases, thus decreases the possibility of a double spend. On the other hand, with the increase in the computing resources (or the so-called hash power) of a miner, the probability of the success of a double spend increases. This leads to a variant of double spend attack called > 50% attack or Goldfinger attack [36] in which more than 50% computing resources of the network are under the control of a single miner. The > 50% attack is considered the worst-case scenario in the Bitcoin network because it has the power to destroy the stability of the whole network by introducing the actions such as claim all the block intensives, perform double spending, reject or include transactions as preferred, and play with the Bitcoin exchange rates. The instability in network, once started, it will further strengths the attackers position as more and more
honest miners will start leaving the Bitcoin network.

From the above discussion on various type of double spending attacks, we can safely conclude that one can always perform a double spend or it is not possible to entirely eliminate the risk of double spending in Bitcoin. However, performing double spending comes with certain level of risk, for instance the attacker might lose the reward for the withheld block, if it is not included in the final public blockchain. Therefore, it is necessary to set a lower bound on the number of double spend coins, and this number should compensate the risk of unsuccessful attempts of double spend. Additionally, the double spends could be recognized with the careful analysis and traversing of the blockchain, thus it might lead to blacklisting the detected peer. In Section IV-A, we will discuss in detail, the existing solutions and their effectiveness for detecting and preventing the double spending attacks.

B. Mining Pool Attacks

Mining pools are created in order to increase the computing or hash power which directly effects the verification time of a block, thus it increases the chances of winning the mining reward. For this purpose, in recent years, a large number of mining pools have been created, and the research in the field of miner strategies is also evolved. At the same time, the attack vector that exploits the vulnerabilities in pool based mining also increases. For instance, a group of dishonest miners could perform a set of internal and external attacks on a mining pool. Internal attacks are those in which miners act maliciously within the pool to collect more than their fair share from a collective reward or disrupt the functionality of the pool to distort it from the successful mining attempts. In external attacks, miners could use their higher hash power to perform attacks such as double spending on the Bitcoin network. Figure 7 shows the market share till March, 2017 of the most popular Bitcoin mining pools. In this section, we will discuss a set of popular internal and external attacks on the mining pools.

![Fig. 7. Mining Power Distribution in Present Market](image)

In [41], authors uses a game theoretic approach to show that in the current Bitcoin payment system, the miners could have a specific sort of subversive mining strategy called selfish mining [42] or also popularly known as block discarding attack [41] [32]. In truth, all the miners in the Bitcoin are selfish as they are mining for the reward that is associated with each block, but these miners are also honest and fair with respect to the rest of the Bitcoin miners, while the selfish mining here refers to the malicious miners only. In the selfish mining attack, the dishonest miner(s) perform information hiding (i.e., withhold a mined block) as well as perform its revealing in a very selective way with a two-fold motive: (i) obtain an unfair reward which is bigger than their share of computing power spent, and (ii) confuse other miners and lead them to waste their resources in a wrong direction. By keeping the mined block(s), the selfish miners intentionally forks the blockchain. The selfish pool keep on mining on top of their private chain \( B_{fork}' \), while the honest miners are mining on the public chain \( B_{fork} \). If the selfish miners are able to take a greater lead on \( B_{fork}' \) and they are able to keep the lead for a longer time period, their chances of gaining more reward coins as well as the wastage of honest miners resources increases. As soon as the \( B_{fork} \) reaches to the length of \( B_{fork}' \), the selfish miners publish their mined blocks. All the miners will lose their rewards for the blocks that they have mined and added on the previous public chain. The analysis presented in [42], shows that using the selfish mining, the pool’s reward exceed its share of the network’s mining power. The wastage of computing resources and rewards lure honest miners toward the selfish mining pools, thus it further strengthen the attack. This continuous increase in the selfish pool’s size might lead to > 50\%attack at that point the effect of selfish mining will be disastrous.

The Pool Hopping attack presented in [23] [77] can be considered as a type of selfish mining. In this attack, the adversary perform continuous analysis of the number of shares submitted by fellow miners to the pool manager in order to find (i.e., publish) a block. The idea is that if already a large number of shares have been submitted and no block has been found so far, the adversary will be getting a very small share from the reward because it will be distributed based on the shares submitted. Therefore, at some point of time it might be more profitable for the adversary to switch to another pool or mine independently. Another attack much similar to the block discarding attack that could be performed on a mining pool by a malicious miner is known as Block withholding [23] [47], in which a pool member never publishes a mined block in order to sabotage the pool revenue. In [23], two type of block withholding scenarios are presented called “Sabotage” and “Lie in wait”. In first scenario, the adversary does not gain any coins, but it just makes other pool members to loose, while in second scenario, the adversary performs a complex block concealing attack similar to the one described in the selfish mining attack. In [23], authors discuss a generalized version of the “Sabotage” attack which shows that with slight modification, it is possible for the malicious miner to also earn additional profit in this scenario. Authors in [78] present a game-theoretic approach to analyze effects of block withholding attack on mining pools.
The analysis shows that the attack is always well-incentivized in the long-run, but may not be so for a short duration. This implies that existing pool protocols are insecure, and if the attack is conducted systematically, Bitcoin pools could lose millions of dollars worth in just few months.

Recently, the Bribery attack is described in [48]. In this attack, an attacker might obtain the majority of computing resources (i.e., mining capacity) for a short duration via bribery. Authors discuss three ways to introduce bribery in the network: (i) Out-of-Band Payment, in which the adversary pays directly to the owner of the computing resources and these owners then mine blocks assigned by the adversary, (ii) Negative-Fee Mining Pool, in which the attacker forms a pool by paying higher return, and (iii) In-Band Payment via Forking, the attacker attempts to bribe through Bitcoin itself by creating a fork containing bribe money freely available to any miner adopting the fork. By having the majority of the hash power, the attacker could launch different attacks in the Bitcoin such as double spending and Distributed Denial-of-Service (DDoS) [79]. The miners that took the bribes will get benefit which will be short-lived, but these short-lived benefits might be undermined by the losses in the long run due to the presence of DDoS and Goldfinger attacks or via an exchange rate crash in the network.

In [50], authors present a malicious mining strategy called feather forking, in which a dishonest miner attempts to blacklist one or more transactions from a client by publicly announcing not to extend a blockchain if it contains one of the blacklisted transaction, thus it will retaliate by forking the chain. The adversary forks as per its convenience, and it will continue to extend its fork until it wins (i.e., outraces the main chain), but if it is losing (i.e., falls behind as compared to main chain by a predefined n blocks) than it discard its fork and continue to extend the main chain. An adversary with total hash power less than 50% might, with high probability, lose rewards, but it will be able to block the blacklisted transaction with positive probability. Moreover, if the adversary can show that he is determined to block the selected transaction and will perform the retaliatory forking if required, than the rest of the miners will also be motivated to block the blacklisted transactions to avoid the losses, in case, if the attacker retaliates and wins. If this is the case, an attacker might be able to enforce the selective blacklisting with no real cost because other miners are convinced that the attacker will perform a costly feather forking attack if provoked. An attacker performing feather forking can also use it to blackmail a client by threatening that all her transactions will be put into the blacklist until the client pays the asked ransom coins.

C. Client-side Security Threats

The huge increase in the popularity of Bitcoin encouraged a large number of new users to join the network. Each Bitcoin client possess a set of private-public keys in order to access its Bitcoin account or wallet. This requires secure, yet usable, key management techniques because unlike many other applications of cryptography, if the keys of a client are lost or compromised, the client will suffer immediate and irrevocable monetary losses. To use Bitcoin, a user need to install a wallet in her desktop or mobile device. The wallet stores the set of private-public keys associated with the owner of the wallet, thus it is essential to take protective actions to secure the wallet. The wallet thefts are mainly performed using mechanisms that includes system hacking, installation of buggy software, and incorrect usage of the wallet.

Bitcoin protocol relies heavily on elliptic curve cryptography [80] for securing the transactions. In particular, Bitcoin uses elliptic curve digital signature algorithm (ECDSA) which is standardized by NIST [81] for signing the transactions. For instance, consider the standard “Pay-to-PubKeyHash” (P2PKH) transaction script in which the user needs to provide her public key and the signature (using her private key) to prove the ownership. To generate a signature, the user chooses a per-signature random value. For security reasons this value must be kept secret, and it should be different for every other transaction. Repeating per-signature value risks the private key computation, as it has been shown in [82] that even partially bit-wise equal random values are suffice to derive a user’s private key. Therefore, it is essential for increasing the security of ECDSA to use highly random and distinct per-signature values for every transaction signature.

The inspection of the blockchain for instances, in which the same public key uses the same signature nonces for multiple times has been reported by the authors in [83]. In particular, the authors report that their are 158 public keys which has reused the signature nonce in more than one transaction signature, thus making it possible to derive user’s private keys. Recently, authors in [84] presents a systematic analysis on the effects of broken primitives on Bitcoin. Authors highlight the fact that in the current Bitcoin system no migration plans are in-place for both the broken hash and the broken signature scheme i.e., the Bitcoins RIPEMD160, SHA256, and ECDSA techniques are vulnerable to various security threats such as collision attacks [85]. The authors in [84] found that the main vectors of attack on Bitcoin involve collisions on the main hash or attacking the signature scheme, which directly enable coin stealing. However, a break of the address hash has minimal impact, as addresses do not meaningfully protect the privacy of a user.

Unlike most of the online payment systems that relies on login details consisting of password and other confidential details for user authentication, Bitcoin relies on public key cryptography. This arises the issues of the secure storage and management of the user keys. Over the years, various type of wallet implementations are researched to obtain secure storage of the user keys, it includes software, online or hosted, hardware or offline, paper and brain wallets. Table II shows a number of popular wallets and their main features. Coinbase (coinbase.com), an online wallet is most popular due to its desirable features which it provides to the clients that includes: (i) a web interface using which the wallet can be assessed with a browser and Internet connection, (ii) a mobile app that allows access to wallet through mobile devices, (iii) an access to Coinbase does not require a client software and it is independent in nature due to which the wallet manufacture does not have any control on the funds stored in a client’s

wallet, and (iv) a moderate level of security and privacy. The Copay wallet allows multiple users to be associated with the same wallet, while the Armory wallet works in online as well as in offline mode. The wallet manufacturers have to find an adequate trade-off between usability and security while introducing a new wallet into the market. For instance, an online wallet is more susceptible to thefts compared to hardware wallets [57] as later are not connected to Internet, but at the same time hardware wallets lacks usability. If done right, their exists more advanced and secure ways to store the user keys called paper and brain wallets. As their name indicates, in paper wallet the keys are written on a document which is stored at some physical location analogizes the cash money storage system, while in brain wallet the keys are stored in the clients mind in the form of a small passphrase. The passphrase if memorized correctly is then used to generate the correct private key.

To avoid the aforementioned risks such as managing cryptographic keys [86], lost or stolen devices, equipment failure, Bitcoin-specific malware [87], to name a few, that are associated while storing the coins in a wallet, many users might prefer to keep their coins with online exchanges. However, storing the holdings with an exchange makes the user vulnerable to the exchange systems. For instance, one of the most notorious event in the Bitcoins history is the breakdown and ongoing bankruptcy of the oldest and largest exchange called Mt. Gox, which lost over 450M US dollars. Moreover, a few other exchanges have lost their customers’ Bitcoin savings and declared bankruptcy due to external or internal theft, or technical mistakes [88]. Although, the vulnerability of an exchange system to the disastrous losses can never be fully avoided or mitigated, therefore the authors in [89] presents Provisions, which is a privacy-preserving proofs of solvency for Bitcoin exchanges. Provisions is a sensible safeguard that requires the periodic demonstrations from the exchanges to show that they controls enough Bitcoins to settle all of its customers accounts.

D. Attacks on Bitcoin Protocols and Networking Infrastructure

In this section, we will discuss those attacks in the Bitcoin that exploits, the existing vulnerabilities in the implementation and design of the Bitcoin protocols and its peer-to-peer communication networking protocols. We will start our discussion with the most common networking attack called Distributed Denial-of-Service (DDoS) attack which targets Bitcoin currency exchanges, mining pools, eWallets, and other financial services in Bitcoin. DDoS attacks are inexpensive to carry out, yet quite disruptive in nature. In these attacks, the adversary exhaust the network resources in order to disrupt their access to genuine users. For example, a honest miner is congested with the requests (such as fake transactions) from a large number of clients acting under the control of an adversary. After a while, the miner will likely to start discarding all the incoming inputs/requests including requests from honest clients. In [62], authors provide a comprehensive empirical analysis of DDoS attacks in the Bitcoin by documenting the following main facts: 142 unique DDoS attacks on 40 Bitcoin services and 7% of all known operators were victims of these attacks. The paper also states that the majority of DDoS target the exchange services and large mining pools, because a successful attack on these will earn huge revenue for the adversary as compared to attacking individual or small mining pools.

In [63], authors explore the trade-off between the two mining pool related strategies using a series of game-theoretical models. The first strategy called construction, in which a mining pool invests for increasing its mining capacity in order to increase the likelihood of winning the next race. While in second strategy called destruction, in which the mining pool launches a costly DDoS attack to lower the expected success rate of a competing mining pool. Majority of the DDoS attacks target large organizations due to bulk ransom motives. Companies like CoinWallet and BitQuick were forced to shutdown only after few months of their launch due to the affects of continuous DoS attacks. As stated above that DoS attack take various forms, one of which discourages a miner so that it will withdraw itself from the mining pool. For instance, an attacker displays to a colleague miner that it is more powerful, and it can snatch the reward of mining, and it is the obvious winner of the mining process. A honest miner backoffs since its chances of winning is less. Hence, an adversary is successful in removing individual miners as well as small pools from the mining network, thus imposing a DoS attack in the network [63]. Moreover, in [90], authors propose network partitioning in Bitcoin peer-to-peer networks, thus isolating the honest nodes from the network by reducing their reputation.

Now we discuss the so called Malleability attacks [53], which also facilitates the DDoS attacks in Bitcoin networks. For instance, by using a Malleability attack an adversary clogs the transaction queue [91]. This queue consists of all the pending transactions which are about to be serviced in the network. Meanwhile, an adversary puts in bogus transactions with the high priority depicting itself to be highest incentive payer for the miners. When the miners try to verify these transactions, they will find that these are the false transaction, and but by this time they have already spent a considerable amount of time in verifying these false transactions. Hence, this attack wastes the time and resources of the miners and the
network [92]. Malleability is defined in terms of cryptography by [53]. A cryptographic primitive is considered malleable, if its output Y can be “mauled” to some “similar” value Y’ by an adversary who is unaware of the cryptographic secrets that were used to develop Y.

In [52], another form of malleability attack called transaction malleability is introduced. In Bitcoin, suppose that a transaction $T_{A \rightarrow B}^n$ which transfers n coins from A’s wallet to B’s wallet, with transaction malleability it is possible to create another $T'$ that is syntactically different (i.e., $T_{A \rightarrow B}^{n'}$ and $T'$ has different transaction hash ID $T^{id}_{A \rightarrow B}$), although semantically it is identical (i.e. $T'$ also transfers n coins from wallet A to B). An adversary can perform transaction malleability without even knowing the private key of A. On a high level, transaction malleability refers to a bug in the original Bitcoin protocol which allows the aforementioned behavior in the network possible. The main reason is that, in Bitcoin each transaction is uniquely identified by its $T^{id}$, and hence in some cases $T'$ will be considered a different transaction than $T_{A \rightarrow B}$.

In Bitcoin, of course, transaction malleability is not desirable, but it does not cause any damage to the system until an adversary exploit its behavior and make someone believe that a transaction has been failed, although after a while it gets published in the global blockchain. This might lead to a possible double spend, but it is particularly more relevant while targeting the Bitcoin exchanges which holds a significant amount of coins because these allows the Bitcoin users to buy and sell coins in exchange of cash money or altcoins. The Bitcoins reference implementation is immune to the transaction malleability because it uses previous transaction’s outputs as an indication for a successfully issued transactions. However, few exchanges use a custom implementation and were apparently vulnerable. For instance, Mt. Gox (a popular exchange) issued a statement in the early days of Bitcoin that they were attacked due to transaction malleability, therefore they are forced to halt withdrawals and freezing clients account. The attack that MtGox claimed to be the victim proceeds as follows: (i) an dishonest client $C_d$ deposits n coins in his MtGox account, (ii) $C_d$ sends a transaction T to MtGox asking to transfer her n coins back, (iii) MtGox issues a transaction $T'$ which transfers n coins to $C_d$, (iv) $C_d$ performs the malleability attack, obtaining $T'$ that is semantically equivalent to T but has a different $T^{id}$, now assume that $T'$ gets included into the blockchain instead of $T$, (v) $C_d$ complains to MtGox that the transaction T was not successful, (vi) MtGox performs an internal check, and it will not found a successful transaction with the $T^{id}$, thus MtGox credits the money back to the user’s wallet. Hence effectively $C_d$ is able to withdraw her coins twice. The whole problem is in the above Step (vi), where MtGox should have searched not for the transaction with $T^{id}$ of T, but for any transaction semantically equivalent to T.

Due to the vulnerabilities that exist in the refund policies of the current Bitcoin payment protocol, a malicious user can perform the so-called Refund attacks. In [49], authors present the successful implementation of the refund attacks on BIP70 payment protocol. BIP70 is a Bitcoin community-accepted standard payment protocol that governs how vendors and customers perform payments in Bitcoin. Most of the major wallets use BIP70 for coin exchanges, and the two dominant Payment Processors called Coinbase and BitPay, who uses BIP70 and collectively they provide the infrastructure for accepting coins as a form of payment to more than 100,000 vendors. The authors propose two types of refund attacks called Silkroad Trader attack which highlights an authentication vulnerability in the BIP70, and Marketplace Trader attack which exploits the refund policies of existing payment processors. The brief description of both the refund attacks is as follows:

- In the Silkroad attack, a customer is under the control of an ill trader. When customer starts trading with the merchant, its address is revealed to the ill trader. When the transaction is finished, the adversary initiates attack by inserting the customers address as the refund address and send a refund request to the merchant. The merchant send the amount to the ill trader, and hence gets cheated without receiving refund from the other side. During this whole process of refund between the merchant and the ill trader, the customer is not at all aware of the fraud that is happening in her name.

- The Marketplace trader attack is a typical case of the man-in-the-middle attack. In this, the adversary setup an attractive web-page, where she attracts customer who fall victim in the later stages. The attacker depicts himself as a trusted party by making payments through trust-able merchants like CEX. When a customer clicks the web-page, accidentally she reveals her address among the other identities that are sufficient to perform malpractice by the rogue trader with the false web-page. When customer purchase products, a payment page is sent which is of a legitimate payment exchange merchant. The end merchant is connected to the adversary’s web-page and meanwhile, the details of the customer would have been already revealed to the attacker, through an external email communication according to the Bitcoin refund policies. After the transaction, the middle adversary claims a refund on behalf of the customer, and the refund amount will be sent to the rogue adversary’s account. Hence, the legitimate customer will not be aware of the fraud process, but the merchant loses his coins [49].

Later, both these attacks have been acknowledged by Coinbase and Bitpay with temporary mitigation measures put in place. However, the authors claim that to fully address the identified issues will require revising the BIP70 standard.

Yet another attack on the Bitcoin networks is called Time jacking attack [59]. In Bitcoin network, all the participating nodes internally maintains a time counter that represents the network time. The value of the time counter is based on the median time of a node’s peers, and it is sent in the version message when peers first connect. However, if the median time differs by more than 70 minutes from the system time, the network time counter reverts to the system time. An adversary could plant multiple fake peers in the network, and all these peers will report inaccurate timestamps, thus it can potentially slow down or speed up a node’s network time counter. An advanced form of this attack would involve speeding up the
clocks of a majority of the network’s mining resources while slowing down the target’s clock. Since the time value can be skewed by at most 70 minutes, the difference between the nodes time would be 140 minutes [59]. Furthermore, by announcing inaccurate timestamps, an attacker can alter a node’s network time counter and deceive it into accepting an alternate announcement of inaccurate timestamps, an attacker can alter a node’s clocks of a majority of the network’s mining resources while slowing down the target’s clock. Since the time value can be skewed by at most 70 minutes, the difference between the nodes time would be 140 minutes [59]. Furthermore, by announcing inaccurate timestamps, an attacker can alter a node’s network time counter and deceive it into accepting an alternate blockchain because the creation of new blocks heavily depends on network time counters. This attack significantly increases the possibility of the following misbehaviors: a successful double spending attack, exhaust computational resources of miners, and slow down the transaction confirmation rate.

Apart from the aforementioned major attacks on Bitcoin protocol and network, there are few other minor attacks that we are summarized below.

- **Sybil Attack**: A type of attack, where attacker installs dummy helper nodes and tries to compromise a part of the Bitcoin network. A sybil attack [17] is a collaborative attack performed by a group of compromised nodes. Also, an attacker may change its identity and may launch a collusion attack with the helper nodes. An attacker tries to isolate the user and disconnect the transactions initiated by the user, or a user will be made to choose only those blocks that are governed by the attacker. If no nodes in the network confirm a transaction, that input can be used for double spending attack. An intruder with her helper nodes can perform a collaborated timing attack, thus can hamper a low latency encryption associated with Bitcoin network. The other version of this attack where the attacker tries to track back the nodes and wallets involved in the transaction is discussed in [61].

- **Eclipse attack**: In this attack [65], an adversary manipulates a victim peer. The IP addresses to which the victim user connects are blocked or diverted towards an adversary [65]. In addition, an attacker can hold multiple IP addresses to spoof the victims from the network. An attacker may deploy helpers and launch other attacks in the network such as double spending and selfish mining. The attack could be of two type: (i) Infrastructure attacks, where attack is on the ISP (Internet Service Provider) which holds numerous contiguous addresses, hence it can manipulate multiple addresses that connects peer-to-peer in the network, and (ii) botnet attacks, where an adversary can manipulate addresses in a particular range, especially in small companies which own their private set of IP addresses. In both the cases, an adversary can manipulate the peers in the Bitcoin network.

- **Tampering**: In a Bitcoin network, after mining a block the miners broadcast the information about newly mined blocks. New transactions will be broadcast from time to time in the network. The network assumes that the messages will reach to the other nodes in the Bitcoin network with a good speed. However, authors in [66] ground this assumption, and they prove that the adversary can induce delays in the broadcast packets by introducing congestion in the network or making a victim node busy by sending requests to all its ports. Such type of tampering can become a root cause for other types of attacks in the network.

IV. SECURITY: COUNTERMEASURES FOR BITCOIN ATTACKS

In this section, we discuss the state-of-the-art security solutions that provides possible countermeasure for the array of Bitcoin attacks presented in Section III.

A. No more double spending

Bitcoin’s default solution against double spending is to use its Proof-of-Work (PoW) technique, which limits the capabilities of an adversary in terms of her computational resources. The concept of PoW also protect the network against being vulnerable to sybil attacks which, if launched it could sabotage the functionality of consensus algorithm and leads to possible double spending attack. In general, double spending could be dealt in two possible ways: (i) detect a double spending instance by monitoring the blockchain progress, and once detected, identify the adversary and take adequate actions, or (ii) use preventive measures. The former approach works well in traditional centralized online banking system, but in Bitcoin its not suitable due to the use of continuously varying public keys as a wallet address, thus it provides anonymity to users, and the lack of transaction rollback scheme once it is successfully added in the blockchain. Therefore, the later approach i.e., prevent double spend, is desirable in Bitcoin.

Authors in [29] evaluate three techniques that can be used to detect a possible double spending in fast payment systems namely: using a listening period, inserting observers, and forwarding double spending attempts. In the first technique, the vendor associates a listening period with each received transaction, and it monitors all the receiving transactions during this period. The vendor only delivers the product, if it does not see any attempt of double spending during its listening period. The inserting observers technique naturally extends the first technique based on the adoption of listening period would be for the vendor to insert a set of nodes (i.e., “observers”) under its control within the Bitcoin network. These observers will directly relay all the transactions to the vendor that they receive from the network. In this way, with the help of the observers, the vendor is able to see more number of transactions in the network during its listening period, thus increases the chances of detecting a double spend. The third technique (i.e., forwarding double spending attempts) requires each Bitcoin peer to forward all transactions that attempt to double spend instead of discarding them, so that the vendor can receive such a transactions on time (i.e., before releasing the product). With this approach, whenever a peer receives a new transaction, it checks whether the transaction is an attempt to double spend, if so, then peer forward the transaction to their neighbors (without adding it to their memory pools).

Recently, the hash power of a pool called GHash.IO reached to 54% for a day (i.e., it exceeds the theoretical attack threshold of 51% in Bitcoin). Although the GHash.IO remained honest by transferring a part of its mining power to other pools. But the incentives that motivates an adversary to create large pools
remains in the network, looking for a chance to wrongful gain and disrupt the network. Therefore, a method to prevent the formation of large pools called Two phase Proof-of-Work (2P-PoW) has been proposed in [38]. The authors propose a second proof-of-work (say $Y$) on top of the traditional proof-of-work (say $X$) of the block header. $Y$ signs the produced header with the private key controlling the payout address. Similar to existing hashing procedures this signature must meet a target set by the network, thus the use of $Y$ forces pool managers to distribute their private key to their clients if the manager wants to retain the same level of decentralisation. However, if a manager would naively share its private key, all clients would be authorised to move funds from the payout address to any destination. Pool managers unwilling to share their private key therefore need to install mining equipment needed to solve $Y$ in a timely manner. It is estimated that GHash.IO owns only a small percentage of the networks computing power in hardware, as the pool shrunk significantly after public outrage. Depending on the difficulty $Y$’s cryptographic puzzle, this would only allow a certain number of untrusted individuals to join. This would, as GHash.IO is a public pool, severely limit its size.

Another solution to control double spending was proposed in [93] where all the participating users deposit a safety amount similar to an agreement. If an attacker tries to double spend and it is detected, the deposit amount will be deducted and given to the victim who encountered the loss. Due to the punishing attribute of the network, the attack can be controlled. In [32], authors suggest an countermeasure by prohibiting the merchant to accept incoming connections, thus an adversary cannot directly send a transaction to the merchant. This forces the adversary to broadcast the transaction over the Bitcoin network, and it ensures that the transaction will end-up in the local view of all the miners that forwards it. Later if the adversary tries to double spend the miners will know about it.

Solution for 50% attack is presented in [32]. The authors provide countermeasures for two variants of 50% attack namely: block discarding attack and difficulty rising attack. In block discarding attack, an adversary has control over a set of nodes in the network, called supporters. The adversary and her supporters purposefully add delay to the legitimate block, and the attacker advertise her block selfishly. Hence, the advertiser’s blockchain will increase, and the other blocks due to delay gets less attention. The delay becomes worse as the number of supporter increases. The solution for this attack is fixing the punishment for the advertisers or the misbehaving miners. Every node is asked to pay a deposit amount, and the nodes that misbehave are punished by dissolving the deposit amount of the concerned. This amount is distributed among the nodes who informs about the misbehaving node in the network. In difficulty rising attack, the attacker manipulates the network and slowly rises the difficulty level for the miners. An attacker poses a threat to the network with high hash-power compared with other nodes in the network. The solution to this attack is same as that of block discarding attack. In [94], authors propose a method called “proof-of-reputation”, where the honest miners will get a token based on the current market value. The number of tokens issued can vary with the market value. If the miner has the token, he will be reputed in the mining market pool. The token has a value, and according to which the coins are deposited from all the miners from time to time and is fixed by the network. More the reputation of the miners chain, more the other blocks merge with that chain.

For now, it is safe to conclude that their is no solution available in literature that guarantees the complete protection from double spending in Bitcoin. The existing solutions only make the launching of double spending attack more difficult for the adversary. In particular, double spending is an attack that is well discussed in the Bitcoin community, but very few solutions exists so far, and it remains an open challenge for the researchers. The easiest, yet most powerful way for a vendor to avoid a double spend is to wait for more number of confirmations before accepting a transaction. Therefore, each vendor or merchant of the Bitcoin has to set a trade-off between the risk and the product delivery time caused while awaiting for appropriate number of confirmations. Similar to the honest Bitcoin users, there is also a trade-off for the adversary as she needs to consider the expenses (i.e., the loss of computing resources and rewards for the pre-mined blocks) if the attack fails.

B. Countermeasures for Private Forking and Pool Attacks

When a dishonest miner intentionally forks the blockchain by privately mining a set of blocks, it makes the Bitcoin network vulnerable to a wide range of attacks such as selfish mining, block-discarding attack, block withholding attack, bribery attacks to name a few. The aim of these attacks is to cheat Bitcoins mining incentive system. Therefore, at any point of time, detecting and mitigating the faulty forks from the set of available forks posses a major challenge for Bitcoin protocol developers. The simplest solution to handle the selfish mining is suggested in [42]. The authors propose a simple, backward-compatible change to the Bitcoin protocol. In particular, when a miner encounter the presence of multiple forks of same length, it will forward this information to all its peers, and it randomly chooses one fork to extend. In this way, each miner implementing the above approach for selecting a fork to extend will decrease the selfish pool’s ability to increase the probability that other miners will extend their fork through control of data propagation.

To further extend the countermeasure presented in [42], authors in [45] introduce the concept of Freshness Preferred (FP), which places the unforgeable timestamps in blocks and prefer blocks with recent timestamps. This approach uses Random Beacons [95] in order to stop miners from using timestamps from the future. As the selfish miners uses strategic block withholding technique, the proposed strategy will decrease the incentives for selfish mining because withheld blocks will lose block races against newly minted or “fresh” blocks. A similar, but more robust solution for selfish mining that requires no changes in exiting Bitcoin protocol is proposed in [43]. The authors suggest a fork-resolving policy that selectively neglect blocks that are not published in time, and it appreciate blocks that includes pointer to competing blocks of their predecessors. Therefore, if the secretly mined block is not published in
the network until a competing block is published, it will contribute to neither or both branches, thus it gets no benefits in winning the fork race.

Unlike most of the aforementioned solutions against malicious forking, authors in [44] propose a timestamp-free prevention of block withholding attack called ZeroBlock. In ZeroBlock, if a selfish miner keeps a mined block private more than a specified interval called \textit{mat}, than later when this block is published in the network it will be rejected by honest miners. The key idea is that each consecutive block must be published in the network, and it should be received by honest miners within a predefined maximum acceptable time for receiving a new block (i.e., \textit{mat} interval). In particular, an honest miner either receives or publishes the next block in the network within the \textit{mat} interval. Otherwise, to prevent the block withholding, the miner itself generates a specific block called \textit{Zeroblock}. For forking attacks that are internal to a pool, authors in [41] suggest that the only viable option to countermeasure a block withholding attack launched within a pool, is that, the pool managers should involve ONLY miners which are personally known to them, hence they can be trusted. The pool manager should simply dissolve and close a pool, as soon as the earning of the pool goes lower than expected from its computational effort.

In [48], bribery attack is discussed along with its countermeasure. In bribery, an attacker bribe a miner to rent her computing resources, thus it increases the attackers hash power that it could use to launch various attacks in Bitcoin networks. As a countermeasure, authors suggest the use of anti-payment (i.e, counter-bribing) to pool miners which has value more than what attackers are paying to these miners to perform malicious behaviour. However, the drawback is that a legitimate pool manager has to spend a lot to take miners toward the normal mining routine. In addition, as the number of bribing node or a node’s bribe amount increases, the capital requirements for the manager also increases, and as the crypt math becomes more and more difficult the bribe amount increases, thus makes it difficult for the manager to keep the process of counter-bribing active for longer periods.

C. Securing Bitcoin wallets

A wallet contain private keys, one for each account [86]. These private keys are encrypted using master key which is a random key, and it is encrypted using AES-256-CBC with a key derived from a passphrase using SHA-512 and OpenSSLs EVP\_BytesToKey [96]. Private key combined with the public key generates a digital signature which is used to transact from peer-to-peer. Bitcoin uses ECDSA (Elliptic Curve Digital Signature Algorithm) algorithm for encryption, and it is modified in [83] for secret sharing and threshold cryptography.

A manual method of wallet protection was proposed by [97] called a “cold wallet”. A cold wallet is another account that holds the excess of amount by the user. This method uses two computers (the second computer has to be disconnected from the Internet), and using the Bitcoin wallet software a new private key is generated. Excess amount is sent to this new wallet using user’s private key. Authors in [97] claim that if the computer is not connected to Internet, the hackers will not get to know the keys, thus the wallet safety can be achieved. Securing wallets with new cryptographic algorithms apart from ECDSA is still an open issue and a challenge. In [98], an article states that US government have launched their own Bitcoin networks with multi-factor security which incorporates fingerprint biometrics for wallet protection. The device is a standalone tool same as the size of a credit card.

In [57], authors propose BlueWallet, a proof-of-concept based hardware token for the authorization of transactions in order to protect the Bitcoin private keys. The concept is similar to the use of the “cold wallet”, that is, it use a dedicated hardware not connected to the Internet to store the private keys. The hardware token communicates with the computer (or any other device) that creates the transaction using Bluetooth Low Energy (BLE) and it can review the transaction before signing it. The securely stored private key never leaves the BlueWallet and is only unlocked if the user correctly enters her PIN. BlueWallet provides the desired security on the expense of the usability, as the users have to invest and keep an additional device while making a transaction.

Bitcoin already have a built-in function to increase the security of its wallets called “multi-signature”, which tightens the security by employing the splitting control technique. For instance, BitGo - an online wallet, provides 2-of-3 multi-signature transactions to its clients. However, the drawback of using the multi-signature transactions, is that, it greatly compromises the privacy and anonymity of the user. Authors in [55], proposes an efficient and optimal threshold Digital Signature Algorithm (DSA) scheme for securing Bitcoin keys. The main idea behind the use of threshold signatures proposed in [55] is derived from secret sharing [99], in which the private key is split into shares. Any subset of the shares that is equal to or greater than a predefined threshold is able to reconstruct the private key, but any subset that is smaller will gain no information about the key. The main property of threshold signatures [56] is that the key is never revealed because the participants directly construct a signature. Recently, authors in [56] present a TrustZone\textsuperscript{6} based Bitcoin wallet and shows that it is more resilient to dictionary and side-channel attacks. Although, the use of TrustZone make use of the encrypted storage, thus the writing and reading operations become slower.

D. Securing Bitcoin Protocol and Network

In this section, we will discuss various existing countermeasures proposed for securing the Bitcoin’s core protocol stack and its peer-to-peer networking infrastructure functionalities against an array of security threats some of which we have presented in Section III-D.

1) DDoS Attacks: In [63], authors propose a game theoretic approach for analyzing the DDoS attacks. The game assumes that the pools are in competition with each other because the larger pools are always weighted more than the smaller

\textsuperscript{6}TrustZone is a technology that is used as an extension of processors and system architectures to increase their security.
pools. The game exists between the pools, and each pool tries to increase their computational cost over others, and then it imposes a DDoS attack on the other pools. Hence, authors draw an equilibrium condition between the players, and it concludes that the larger pools have more incentives against the smaller pools. In [100], authors propose a “miner’s dilemma”, again a game theoretical approach on the behavior of miners similar to repetitive prisoner’s dilemma. There exist a game between the Bitcoin pools. The longest chain dominates over the smaller chains and grabs the rewards by behaving selfishly in the network. Game theory concludes that by performing attacks, the pools actually lose the Bitcoins that they are suppose to get, when compared it with the case without attacking each other. In particular, these kind of game theory problems are called “Tragedy of Commons”, where the peers turn out to be rational, selfish, and harm other peers for their benefits.

In [64], author’s proposes Proof-of-Activity (PoA) protocol, which is robust against a DoS attack that could be launched by broadcasting a large number of invalid blocks in the network. In PoA, each block header is stored with a crypt value, and the user that stores the first transaction places this value. These users are called “stakeholders” in the network and they are assumed to be honest. Any subsequent storage of transactions to this block is done if there are valid stakeholders associated with the block. Storage of crypt value is random, and more transactions are stored, only if more stake users are associated with the chain. If length of the chain is more, trustworthiness among other peers increases and more miners get attracted towards the chain. Hence, an adversary cannot place a malicious block or a transaction, since all the nodes in the network are governed by stakeholders.

One possible way to mitigate DDoS attacks is to use the technique discussed in [101], which suggests the continuous monitoring of network traffic by using browsers like tor or any user defined web service. Applying machine-learning techniques like SVM and clustering will identify which part of the network is behaving ill. Hence, that part can be isolated from the Bitcoin network until debugged. Other possible methods to protect against DoS attacks include: (i) configure network in a way that malicious packets and requests from unnecessary ports will be prohibited, (ii) implement a third party DoS protection scheme which carefully monitors the network and identify variations in the pattern. We believe that similar approaches could also be implemented in future in Bitcoin networks to countermeasure DoS attacks.

2) Time Jacking and Eclipse Attack: In this attack, an adversary alters the node time, therefore the dependency of a node on network time can be replaced by a hardware oriented system time. The accept time window (for transactions on a node) has to be reduced, making the node recover quicker from the attacks. Time jacking is a dreaded attack that might split the network in multiple parts and hence, it can isolate the victim node. A set of techniques are suggested in [59] to avoid time jacking that includes, use system time instead of the network time to determine the upper limit of block timestamps, tighten the acceptable time ranges, and use only trusted peers. Even a node can be designed to hold multiple timestamps assuming that the attacker may not alter all the timestamps. Node timestamps can be made dependent on the blockchain timestamps [59].

In [65], authors provide techniques to combat eclipse attack which uses an additional procedure to store the IP addresses that are trustworthy. If the users are connected to another peer in the Bitcoin network, they are stored in “tried” variable. The connection of the user with the peers is dependent on the threshold of the trust factor, which varies from time to time. The users can have special intrusion detection system to check the misbehaving nodes in the network. The addresses which misbehaves in the network are banned from connections. These features can prevent the Bitcoin user under eclipse by an attacker(s). In particular, having a check on the incoming and outgoing connections from node can reduce the effect of an eclipse attack.

3) Refund Attacks and Transaction Malleability: In [49], modifications are proposed in the Payment Request message by adding information about the customer such as registered e-mail address, delivery address, and product information. The payment address should be unique for each Payment Request. Each request is associated with a key, and the same key is used for refund, however the use of the additional information might threaten the privacy of the customer. The customer is no longer involved in the information broadcast about the transaction, but the responsibility is to handover the refund to merchant. Hence, all the nodes will learn about the transaction during verification and can identify the attacker easily. In particular, the idea is to provide the merchant, a set of publicly verifiable evidence which can cryptographically prove that the refund address received during the protocol belongs to the same pseudonymous customer who authorised the payment.

In [102], authors propose a manual intervention process that checks the withdrawal transactions to detect a possible malleability attack. Any suspicious pending transactions in the blocks can be seen as a sign of the attack. In addition, all the transactions on the Bitcoin network should have confirmations. In [52], authors show a case of malleability attack on “deposit protocol”, and provide a solution namely new deposit protocol.

4) Reducing Delays in Transactions: In Bitcoin practice, the transactions with large Bitcoins are not usually carried out due to the risk of loosing it or fear of fraudulent activities. Hence, the transaction is broken into a set of smaller transactions. But, eventually it increases the delay in the network due to the time the network spends in validating the transactions. Hence to reduce this delay, authors in [103] suggest payments offline through separate type of transactions called “micropayments” [104] and via a separate channel called micropayment channel. This channel is not a separate network but part of bitcoin network itself. In a traditional bitcoin network, users broadcast their transaction and the other miners verify it. This happens for all the transactions, and the network might get clogged at places where large number of transactions exist. Also, in such a situation, the network gives preference to transactions with large denomination compared to the smaller ones. Hence, by establishing micropayment channels, the separate dedicated channel is allotted for the counter parties to perform the transaction. The basic idea is that the transaction
is not revealed until both the parties trust each other on their balances and transaction that they perform. If either of the one misbehaves, then the transaction is broadcasted for the verification from the Bitcoin network. The channels obey the Bitcoinc protocol and they are established like any other naive network routing techniques. Hence, this micro payment channels constitute a “lightning network”. The advantages of using a lightning network is as follows:

- The technique provides high speed payments, eliminates the dependency on the third party to validate, reduced load on the bitcoin network, channels can stay open indefinetly for the transactions, counter parties can move out of the agreement whenever they want, parties can sign using multiple keys.
- Parties can broadcast their information when they want for seeking the interference of the other miners to solve the discrepancies.
- Parties can send their transaction over the channel without revealing their identities to the network and the nodes helping in routing.
- Payments an be routed across many block chains. Network allows micro level payment transactions.

5) Tampering: In [66], author’s provide solutions for tampering attacks. A node can announce the time it takes to mine a block together with the advertisement of a new block. This makes another peer in the network approximate estimate the average time needed to mine a block, and hence no one can spoof by adding unnecessary delays or tampering timestamps. Instead of static timeouts, dynamic timeouts can make more sense, since mining time can vary from node to node. All the senders buffer the IP addresses with which it is connecting every time, and this avoids the IP sending same advertise messages again and again to the same peer. A track of all the nodes has to be recorded in every sender and pattern can be analyzed. If a transaction is not replied by a node in a time window, then the sender will ask other nodes to confirm the transaction.

Despite all the security threats and their solutions that we have discussed, the number of miners in a network is a factor of consideration. More the miners, more people to verify the transactions, hence faster the block validation process, and more efficient the consensus process. However, the miners are incentive driven, hence the reward coins can pull more miners into the process, but at the same time the reward reduces half for every four years, thus the miners may migrate towards other cryptocurrencies which offers them more reward coins.

Bitcoin’s consensus algorithm has been its most widely debated component in the Bitcoin research community. This is because the consensus algorithm rises: (i) open questions about the Bitcoin stability [2]; (ii) concerns about the performance and scalability of the protocol [105]; and (iii) concerns that its computational puzzle wastes computational resources [78].

Discussing the improvements or alternatives for Bitcoin’s consensus algorithm for addressing the above research issues are out of the scope of our survey, hence we direct the inserted users to read the current research trends regarding it in [106] [107] [2]. Similarly, for the same aforementioned reason, in this survey we don’t discuss the alternatives to the proof-of-work such as proof-of-stake [108], proof-of-publication [109], proof-of-burn [110], proof-of-activity [64], to name a few, and for in-depth details we direct interested users to [111] [14].

As the security issues in Bitcoin are closely linked with the user privacy and anonymity, we discuss the threats and their existing countermeasures for enabling privacy and enhancing anonymity for Bitcoin users in detail in the next section.

V. PRIVACY AND ANONYMITY IN BITCOIN

Bitcoin technology upholds itself when it comes to the privacy, but the only privacy that exists in Bitcoin comes from pseudonymous addresses (i.e., public keys) which are fragile and easily compromised through different techniques such as Bitcoin address reuse, “taint” analysis and tracking payments via blockchain analysis methods, IP address monitoring nodes, web-spidering, to name a few. Once broken, this privacy is difficult and sometimes costly to recover. Bitcoin allows its user to trivially generate new Bitcoin addresses (i.e., public keys) for each transaction; this provides a strong privacy as argued in [1]. In a traditional banking system, the transactions are known only by the bank and the involved parties, while in the Bitcoin system the public blockchain reveals all the transaction data to any user connected to the Bitcoin network. The original white paper on Bitcoin claims that, this reveal of transactions information through blockchain does not disclose the identity of the parties involved in these transactions, and in [67] authors clarify that the Bitcoin system does not have any directory to maintain the log and other transaction related information. However, an adversary can associate the offline data such as emails and shipping addresses with the online informations, and it can get the private information about the peers. In particular, Bitcoin offers a partial unlinkability (i.e., pseudonymity), and thus it is possible to link a number of transactions to an individual Bitcoin user by tracing the flow of money through a robust blockchain analysis procedure. In this section, we discuss the various security threats to privacy and anonymity of the Bitcoin users and the corresponding state-of-the-art solutions that are proposed to enhance the same.

A. Blockchain Analysis and Deanonymization

A complete anonymity in Bitcoin is a complicated issue. To enforce anonymity in transactions, the Bitcoin system allow its users to generate multiple set of public keys and it only stores the mapping information of a user to her public keys on the user’s device. As a user can have multiple addresses, hence an adversary who is trying to deanonymize a user in a Bitcoin system needs to construct a one-to-many mapping between the user and its associated public keys. In particular, the Bitcoin users can be linked to a set of public addresses by using a detailed blockchain analysis procedure [112]. Authors in [67] shows that the two non-trivial networking topologies called transaction network and user network, which provides reciprocal views of the Bitcoin system and have possible adverse implications for user anonymity. Similar to the work done in [67], authors in [113] presents an evaluation for privacy concerns in Bitcoin systems by analyzing the public
blockchain. The analysis of blockchain requires three pre-processing steps, which includes:

- **Transaction graph:** The whole blockchain could be viewed as an acyclic transaction graph \( G_t = \{ T, E \} \), where \( T \) is a set of transactions stored in the blockchain, and \( E \) is the set of unidirectional edges between these transactions. A \( G_t \) represents the flow of coins between transactions in the blockchain over time. The set of input and output coins in a transaction can be viewed as the weights on the edges in a \( G_t \). In particular, each incoming edge \( e \in E \) in a transaction carries a timestamp and the number of coins \( (C_i) \) that forms an input for that transaction. Figure 8(a) shows an instance of transaction graph in a blockchain.

- **Address graph:** By traversing the transaction graph we can easily infer the relationship between various input and output addresses (i.e., public keys), and using these relations we can generate an address graph, \( G_a = \{ P, E' \} \), where \( P \) is the set of Bitcoin addresses and \( E' \) are the edges connecting these addresses. Figure 8(b) shows an address graph derived from Figure 8(b).

- **User/entity graph:** By using the address graph along with a number of heuristics which are derived from Bitcoin protocol, the next step is to create an entity graph by grouping addresses that seems to belong to the same user. The entity graph, \( G_e = \{ U, E'' \} \), where \( U \) is a disjoint subset of public keys \( (p) \) such that \( p \in P \) and \( E'' \) are the edges connecting different \( U \)'s to show a directed connectivity between them. Figure 8(c) shows the entity graph derived from Figure 8(b) based on a set of heuristics.

In [113], authors introduce two heuristics that are derived directly from Bitcoin protocols or its common practices. The first is the most widely used heuristic that provides an adequate level of linkability and it heavily depends on the implementation details of Bitcoin protocols, and are termed as *idioms of use* as mentioned in [114]. The *idioms of use* assumes that all the inputs in a transaction are generated by a same user because in practice different users rarely contribute in a single, collaborative transaction. This heuristics also supports the fact that transitive closure can be applied on the transaction graph to yield clusters of Bitcoin addresses. For instance, by applying the above heuristic along with its transitive property on Figure 8(a), one can assume that transactions \( T_{x2} \) and \( T_{x3} \) are initiated by the same user as both shares a common input \( p_5 \), hence the addresses ranging from \( p_3 \) to \( p_6 \) could belong to one user. The second heuristic links the input addresses of a transaction to its output addresses by assuming that these outputs as *change* addresses, if an output address is completely new (i.e., the address has never appeared in the past and it will not be seen in the blockchain to be re-used to receive payments). In Figure 8(a), the addresses \( p_{14} \) and \( p_{18} \) satisfy the second heuristic, and thus these addresses can be clustered with their inputs as shown in the Figure 8(c). Authors in [114] argued that the aforementioned heuristics are prone to errors, in cases where the implementation of Bitcoin protocols change with time, and the traditional Bitcoin network also changes which now consists of more number of mining pools instead of single users. Due to these facts, it is possible that the entity graph might contains a large number of false positives in the clustering process, hence it leads to the further refinements in the above heuristics. To reduce these false positives, authors in [114] suggest the manual inspection process to identify the usage patterns induced by Bitcoin services (such as SatoshiDice). For instance, SatoshiDice requires that the payouts use the same address, therefore if a user spent coins using a change address, the address would receive another input which invalidates the one-time receive property of a change address. Furthermore, in [96] authors exploit the multi-signature addressing technique for the purpose of adverse effect to the user privacy. Authors conclude that even if the Bitcoin addresses are changed, the structure of the change address in a multi-signature transaction can be matched to its input addresses.

Apart from using the adaptable and refined heuristics to match with the constantly changing blockchain usage patterns and Bitcoin services, the adversary needs to take further steps to link the address clusters with the real-world identities once an entity graph with low false positives is created. Authors in [114] perform with high precision the linking of clusters with the online wallets, vendors, and other service providers as one can do several interactions with these entities and...
learn at least one associated address. However, identifying regular users is difficult with the same approach, but the authors also suggest that authorities with subpoena power might even be able to identify individual users since most of the transaction flow passes through their centralized servers. These servers usually require to keep records for customer identities. Furthermore, the use of side-channel information is considered helpful in mapping the addresses. For instance, WikiLeaks, Silk Road, to name a few, uses publicly known addresses, and many service providers such as online sellers or exchange services require the user identify before providing a service. One can also make use of the web crawlers (such as bitcointalk.org) that searches the social networks for Bitcoin addresses [115] [116].

A commercial approach for blockchain analysis could be to use the software BitIodine [117] that offers an automated blockchain analysis framework. Due to its rapid growth in such a short span of time, the Bitcoin networks have become of great interest to governments and law enforcement agencies all over the world to track down the illicit transactions. By predicting that their is a huge market potential for Bitcoin, various companies such as Elliptic, Chainalysis, Numisight, Skr, to name a few, are specializing in “bitcoin blockchain analysis”. These companies provide a set of tools to analyze the blockchain to identify illicit activities and even help identifying the Bitcoin users in the process. Authors in [118] propose BitConeView, a graphical tool for the visual analysis of coin flows in a blockchain. BitConeView allows to graphically track how Bitcoins from the given sources (i.e., transaction inputs) are spent over time by means of transactions and are eventually stored at multiple destinations (i.e., unspent transaction outputs).

Finally, network de-anonymization could be used to link an IP address to a user in the Bitcoin’s peer-to-peer (P2P) network because while broadcasting a transaction the node leaks their IP address. Same as the blockchain analysis, a rigorous way to link IP addresses to hosts is by exploiting the network related information that can be collected by just observing the Bitcoin network. Over the years, multiple deanonymization attacks in which an adversary uses a “supernode” that connects with the active peers and listens to the transaction traffic relayed by honest nodes in the Bitcoin P2P network [68] [119] [67] are proposed. By exploiting the symmetric diffusion of transactions over the network, it is possible to link the Bitcoin users’ public keys to their IP addresses with an accuracy of nearly 30% [68]. Moreover, the use of “supernode” for linking is trivial, hence exploits only minimal knowledge of the P2P graph structure and the structured randomness of diffusion. Therefore, we can hypothesize that even higher accuracies could be achieved by using the more sophisticated network traffic analyzing techniques.

B. Proposals for enabling privacy and improving anonymity

Privacy is not defined as an inherent property in Bitcoin’s initial design, but it is strongly associated with the Bitcoin system. Therefore, in the recent years, an array of academic research [113] [135] [136] [117] which shows various privacy re-related weaknesses in the current Bitcoin protocol has been surfaced. This research triggered a large set of privacy-enhancing technologies [135] [129] [61] [125] [127] [137] [120] [124] aiming at strengthening privacy and improving anonymity in the Bitcoin system without breaking its fundamental design principles. In this section, we discuss these state-of-the-art protocols which works toward the enhancement of privacy and anonymity in Bitcoin systems.

Based on the aforementioned discussion in Section V, it is evident that the public nature of the blockchain poses a significant threat for the privacy of Bitcoin users. Even worse, since funds can be tracked and tainted, no two coins are equal, and fungibility, a fundamental property required in every currency, is at risk. With these threats in mind, several privacy-enhancing technologies have been proposed to improve transaction privacy in Bitcoin. The state-of-the-art proposals (refer Table III) for enabling privacy in Bitcoin can be broadly classified in the following three categories:

- **Peer-to-peer mixing protocols.** In peer-to-peer (P2P) mixing protocols [138] [123] [71], a set of untrusted Bitcoin users simultaneously broadcast their messages to create a series of transactions without requiring any trusted third party. The main feature of a P2P mixing protocol is to ensure sender anonymity within the set of participants by permuting ownership of their coins. The goal is to prevent an attacker which controls a part of the network or some of the participating users to associate a transaction to its corresponding honest sender. The degree of anonymity in P2P protocols depend on the number of users in the anonymity set. Table III shows a range of P2P mixing protocols along with their brief description, advantages, and disadvantages in terms of user anonymity and transaction security. CoinJoin [70], a straightforward protocol for implementing P2P mixing which aims to enhance privacy and securely prevent thefts. In CoinJoin, a set of users with agreed (via their primary signatures) inputs and outputs create a standard Bitcoin transaction such that no external adversary knows which output links with which input, hence it ensures external unlinkability. To prevent theft, a user only signs the transaction if its desired output appears in the output addresses of the transaction. In this way, CoinJoin makes the multiple inputs of a transaction independent from each other, thus it breaks the basic heuristic from Section V-A (i.e., inputs of a transaction belong to the same Bitcoin user). However, CoinJoin has few major drawbacks which includes, limited scalability and privacy leakage due to the need of managing signatures of the involved participants in the mixing set, the requirement of signing a transaction by all its participants make CoinJoin vulnerable to DoS attacks, and to create a mix each participant has to share their signature and output addresses within the participating set which causes internal unlinkability. To address the aforementioned internal unlinkability issue and to increase the robustness to DoS attacks, authors in [71] propose CoinShuffle, a decentralized protocol that coordinates...

<tr>
<td>ByzCoin [133]</td>
<td>Altcoin</td>
<td>Bitcoin-like cryptocurrency with strong consistency via collective signing</td>
<td>lower consensus latency and high transaction throughput, resistance to selfish and stubborn mining [134], eclipse and delivery-tampering and double-spending attacks</td>
<td>vulnerable to slow down or temporary DoS attack and 51% attack</td>
</tr>
</tbody>
</table>
CoinJoin transactions using a cryptographic mixing technique. Later, an array of protocols [120] [121] [123] are built on the concept of either CoinJoin or CoinShuffle that enhances the P2P mixing by providing various improvements that includes, resistance to DoS, sybil, and intersection attacks, plausible deniability, low mixing time, and scalability of the mixing groups.

- **Distributed mixing networks.** Authors in [125] propose MixCoin, a third-party mixing protocol to facilitate anonymous payments in Bitcoin and similar cryptocurrencies. The MixCoin uses the emergent phenomenon of currency mixes, in which a user shares a number of coins with a third-party mix using a standard-sized transaction, and it receives back the same number of coins from the mix that are submitted by some other user, hence it provides strong anonymity from external entities. MixCoin uses a reputation based cryptographic accountability technique to prevent other users within the mix from theft and disrupting the protocol. However, mixes might steal the user coins at any time or become a threat to the user anonymity because the mix will know the internal mapping between the users and outputs. To provide internal unlinkability (i.e., preventing the mix from learning input-output linking) in MixCoin, authors in [126] proposes BlindCoin which extends the MixCoin protocol by using blind signatures to create user inputs and graphically blinded outputs called blinded tokens. However, to achieve this internal unlinkability, BlindCoin requires two extra transactions to publish and redeem the blinded tokens, and the threat of theft from mixes is still present. Recently, in [127] authors propose TumbleBit, a bitcoin compatible unidirectional unlinkable payment hub that allow peers to make fast, off-blockchain payments anonymously over an untrusted intermediary called Tumbler. Similar to Chaumian original eCash protocol [139], TumbleBit enforce anonymity in the mixing by ensuring that no one, not even the Tumbler can link a transaction to its sender to its receiver. The mixing of payments from 800 users show that TumbleBit provides strong anonymity and theft resistance, and it is scalable.

- **Bitcoin extensions or Altcoins.** Instead of proposing techniques (such as mixing and shuffling) to increase transaction anonymity and user privacy in Bitcoin, there are also mechanisms which works as, an extension to Bitcoin or a full-fledged altcoin. Authors in [128] propose ZeroCoin, a cryptographic extension to Bitcoin which provides anonymity by design by applying zero knowledge proofs (ZKP). In ZeroCoin, a user can simply wash the linkability traces from its coins by exchanging them for an equal value of ZeroCoins. But unlike the aforementioned mixing approaches, the user should not have to ask for the exchange to a mixing set, instead the user can itself generate the ZeroCoins by proving that she owns the equal value of Bitcoins via the ZeroCoin protocol. ZeroCoin currently derives both its anonymity and security against counterfeiting from strong cryptographic assumptions at the cost of substantially increased computational complexity and size. The use of zero-knowledge proofs prevent the transaction graph analyses. An extension of ZeroCoin called ZeroCash is presented by [129]. ZeroCash uses an improved version of ZKP (in terms of functionality and efficiency) called SNARKs, which hides additional information about transactions such as amount and recipient addresses to achieve strong privacy guarantees. However, ZeroCash relies on a trusted setup for generation of secret parameters required for SNARKs implementation, it requires protocol modifications, and the blockchain pruning is not possible. Recently, authors in [131] propose MimbleWimble, an altcoin that supports confidential transactions (CT). The CTs can be aggregated non-interactively and even across blocks, thus greatly increases scalability of the underlying blockchain. However, such aggregation alone does not ensure input-output unlinkability against parties who perform the aggregation, e.g., the miners. Additionally, Mimblewimble is not compatible with smart contracts due to the lack of script support.

As a summary, in this section, the Bitcoin systems privacy and anonymity concerns are discussed. It is observed that Bitcoin is pseudo-anonymous, as the account is tied to the keys and not to the individual users. As the need of Bitcoins increases, the need for privacy and anonymity protection also increases, and it must be ensured that the users will receive a satisfactory level of service in terms of privacy, security, and anonymity.

VI. RESEARCH DIRECTIONS IN SECURITY AND PRIVACY OF BITCOINS

In this section, we discuss various issues and open challenges to formulate possible future research directions in Bitcoin. Some of the directives are already discussed in the previous sections. However, remaining challenges are dealt in brief in this section.

- **Game theory and stability:** Recall that mining pools consist of individual miners who pool their hashing power as well as their incentives. Miners can behave selfishly by holding on to their blocks and releasing it whenever they want. This kind of selfish behavior may pose a game theoretic problem between the selfish miners and the network. Since, all the miners perform with a notion of increasing their incentives, a game theoretic approach is well suited for achieving Nash equilibrium among miners (i.e., players) [140]. Attackers may try to contribute in increase of their chain length compared to honest chain in the network. This poses a game between the honest chain miners and the malicious miners, thus achieving equilibrium to bring stability in the network is a possible research direction. There are numerous proposals [140] [141] [142] which shows that the use of the game-theoretic approaches provide useful information about the effects of selfish mining, block withholding and discarding attacks, and the incentive distribution problem in the mining pools. Therefore, we believe that this approach could be effectively used.
for modeling the various issues and providing adequate solutions for the identified issues related to the mining pools.

- **Cryptographic and keying techniques**: The Simplified Payment Verification (SPV) protocol which is a light weight protocol used for the verification of the transaction sent from a user [143], and it is often vulnerable to attacks like sybil and double spending. A more robust verification protocol is a current requirement. For the key manipulations and calculations, a distributed approach is always preferred more than the centralized one. This is to avoid the point of failure or the central server under the risk of an attack. Hence, in this direction the innovative means of key computation and storage of the Bitcoins in a distributed fashion is a possible research direction. Additionally, the Bitcoin protocols uses EDCA and hash functions like SHA-256 which creates another research scope as their is always an adequate requirement to improve these algorithms or implement novel keying and hashing techniques. We have seen the use of cluster or group keys which are based on the some threshold in order to solve various attacks. For instance, fix a group head and get an additional signature or authentication on every transaction [135]. Another approach is to use “trusted paths” which is based on hardware that allow users to read and write a small amount of cryptographic data [135]. Finally, there are few techniques which uses bloom filters for securing wallets. Nevertheless, filters might lead to false positives and false negatives that will consume the network bandwidth, thus reducing it can be a potential research directive.

- **Improving blockchain protocol**: Blockchain provides for the first time a probabilistic solution to the Byzantine generals problem [144], where consensus is reached over time (after confirmations), and makes use of economic incentives to secure the functionality of the overall infrastructure. The blockchain technology promises to revolutionize the way we conduct business. For instance, blockchain startups have received more than one billion dollars [145] of venture capital money to exploit this technology for applications such as voting, record keeping, contracts, to name a few. Despite its potential, blockchain protocol faces significant concerns in terms of its privacy [146] and scalability [105] [147]. The append-only nature of the blockchain is essential to the security of the Bitcoin ecosystem as transactions are stored in the ledger forever and are immutable. However, an immutable ledger is not appropriate for all new applications that are being envisaged for the blockchain. Recently, authors in [148] present modification in blockchain techniques that allows operation such as re-writing one or more blocks, compressing any number of blocks into a smaller number of blocks, and inserting one or more blocks.

- **Fastness**: Bitcoin’s proof of work is designed to validate a new block on average every 10 minutes, and it is recommended to wait for six confirmations before accepting a transaction [149], which makes it impractical for many real world applications (e.g., point of sale payments). Faster mining with the same robustness such as one proposed in [133] is a future requirement. Recently authors in [150] present Proof of Luck, an efficient blockchain consensus protocol to achieve low-latency transaction validation, deterministic confirmation time, negligible energy consumption, and equitably distributed mining.

- **Incentives for miners**: In general, incentives can be either fixed or variable depending on the complexity of the puzzle that miners solve. A variable incentive may increase the competition between the miners and help to solve puzzles that are challenging. The miners who inform the malfunctions and other illegal behavior in the network can be awarded with additional coins as reward. This act will increase the number of honest nodes in the network. In the world of growing demand for the cryptocurrencies, there is lot of competition for Bitcoins or any other digital currency to retain its popularity in the market. Additionally, miners may migrate by looking at the rewards given by the other competitors or by the fact that for every four years the incentives are halved. Therefore, essential questions that needs addressing includes, how to make the miners fix to a currency in such a competitive environment, and what are the other incentives the Bitcoin system can think of to attract the miners.

- **Smart contracts and preventing backtracks**: Smart contracts [151] are of particular interest to those in the financial sector. However, the concept of smart contract is not a new one, but the advent of blockchain technology spurred interest in it because the blockchain eliminates the need to rely on a trusted third party to “execute” the contract, and enables to use of cryptocurrency as “programmable money”. Bitcoins support for smart contracts is extremely limited. Recently authors in [151] propose Hawk, which uses a blockchain model of cryptography to generate privacy-preserving smart contracts. Similar to Bitcoins, authors in [152] proposes Enigma, a decentralized computation platform which provides a highly optimized version of secure multi-party computation with guaranteed privacy to effectively execute smart contracts.

### VII. Conclusions

Bitcoins has already evinced as a popular digital currency in the market. However, the fame of Bitcoins has attracted antagonists to use Bitcoin network for their selfish motives and benefits. Today we have nearly 700 different cryptocurrencies in action, nevertheless the outstanding popularity of Bitcoins makes this currency favorite for hackers. According to our survey, even though the construction of the Bitcoin protocols with proof-of-work and consensus to protect the user actions are the robust features of Bitcoin, these itself becoming a point of manipulation for cyber thieves. Starting from packet sniffing

---

7Computer programs that embody a self-executing and self-enforcing contract to which users may become party, by interacting with it electronically.
to the double spending, the Bitcoin systems are dreaded with various attacks. Though, literature provide solutions against few of these attacks, but the robust and effective security solutions that can ensure proper functioning of the Bitcoin in the future are still absent. Together with security, the distributed nature of Bitcoin’s blockchain protocols has lead glitches in the privacy and anonymity requirements of the users. In summary, this paper is a sole attempt towards highlighting the security and privacy issues in different fields of Bitcoin. Once presenting the major components of Bitcoin, its basic characteristics and related concepts in brief, our survey mainly focuses on the security and privacy aspects that can be found at various stages, starting from transaction creation to its successful addition in the blockchain, in Bitcoin payment systems. We studied and emphasize the issue of user privacy and anonymity in this rapidly growing e-commerce industry. With the set of future research directions and open questions that we have raised, we hope that our work will motivate fledgling researchers towards tackling the security and privacy issues of Bitcoin systems, as we believe that issues with very high practical relevance remains yet to be answered in the area.
